### Abstract

This dissertation focuses on the intelligent robot control in autonomous navigation using reinforcement learning. More precisely, the purpose of this bachelor project is to make a robot adapt its behavior based on traffic light using reinforcement learning. Reinforcement learning is a machine learning paradigm in which the agent tries to maximize a numerical reward signal (the reward function) in the long run and has only partial feed-back from the environment (in opposition with supervised learning where the feed-back is complete and unsupervised learning where there is no feed-back) : indeed the agent is not told which action to take but must discover it by trying the actions and see which one yields the best reward.

To make things a little bit more formal, we will introduce Markov Decision Processes (MDP), and then consider model-based and model-free algorithm to solve the problem of learning from partial feedback of the environment.

Then we will implement on our robot our different algorithm to compare them and then discuss about further work. This project is the successor of many projects on the robot in DISOPT.

# Theory

## 1 MDP : Markov decision processes

Markov's decision processes are a tuple  $\mathcal{M} = \{\mathcal{S}, \mathcal{A}, T, R, \gamma\}$  :

- a set of states :  $\mathcal{S} = \{s_0, s_1, \dots, s_n\}$
- a set of actions :  $\mathcal{A} = \{a_1, a_2, \dots, a_k\}$
- a transition function :  $T(s, a, s') \sim \text{Pr}(s' \mid a, s)$   $s, s' \in \mathcal{S}$  which gives the state transition probabilities
- a reward function :  $R : \mathcal{S} \mapsto \mathbb{R}$
- a discount factor  $\gamma \in [0, 1)$

The discount factor  $\gamma$  helps making our learning agent more or less far-sighted :  $\gamma$  can be interpreted as the relative importance it will give to future rewards compared to immediate ones.

$\mathcal{M}$  is a MDP if it respects the Markovian property which is that the transitions only depends on the current state and action :

$$\mathbb{P}(s_{n+1} \mid a_{n+1}, s_n, a_n, s_{n-1}, \dots) = \mathbb{P}(s_{n+1} \mid a_{n+1}, s_n)$$

When an agent is learning in a MDP, what it observes is a sequence of states, actions and rewards: suppose the agent is in the state  $s_0$  and chooses action  $a_1$  and then end up in state  $s_1$  with reward  $r_1$ ; then the sequence observed is of the form :  $s_0, a_1, s_1, r_1, a_2, s_2, r_2 \dots$

Markov decisions processes can easily be represented as a directed graph : the nodes are the states and the directed edges from a node  $Q$  are the actions an agent can choose to make while being in state  $Q$ , which will bring the agent in the state represented by the node at the endpoint of the edge as we can see in figure 1.

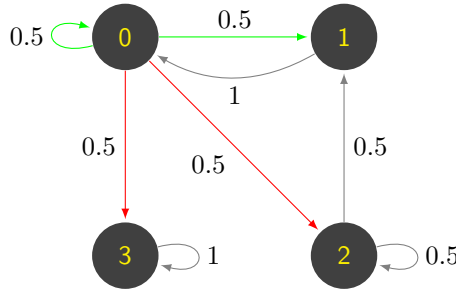

Figure 1: example of a graph representing a Markov Decision process, there are two actions possible from node 0 which takes to different states with some probability

## 2 Policies and Value functions

A policy :  $\pi$  is a stochastic mapping from states to action:

$$\pi : \mathcal{A} \times \mathcal{S} \mapsto [0, 1] \quad \text{s.t.} \quad \sum_a \pi(a \mid s) = 1 \quad \forall s \in \mathcal{S}$$

A policy is a formalisation of the decision making process : in each state, we follow the policy to decide which action to choose with some probability:  $\pi(a \mid s)$  is the probability that  $A_{t+1} = a$  if  $S_t = s$ . Hence maximizing the reward means finding a good policy.

We need to quantify the reward the agent has to maximize, so we define the return as :

$$G_t = r_{t+1} + \gamma r_{t+2} + \dots = \sum_{k=0}^{\infty} \gamma^k r_{t+k+1} = r_{t+1} + \gamma G_{t+1}$$

Now we need a way to compare policy between them : for that we use the *value functions* : the state value and the state-action value under a certain policy  $\pi$ . Intuitively they measure how good it is to be in a state (or respectively to take a specific action while being in a state) if we follow the policy afterwards.

Then we can define the value of taking action  $a$  in state  $s$  while following the policy  $\pi$  as the expected return we would receive if we follow  $\pi$ :

$$\begin{aligned} v_{\pi}(s) &= \mathbb{E}_{\pi}[G_t \mid S_t = s] \\ &= \mathbb{E}_{\pi}[r_{t+1} + \gamma G_{t+1} \mid S_t = s] \\ &= \mathbb{E}_{\pi}[r_{t+1} \mid S_t = s] + \gamma \mathbb{E}_{\pi}[G_{t+1} \mid S_t = s] \\ &= \sum_a \pi(a \mid s) \sum_{s'} \mathbb{P}(s' \mid a, s) R(s') \\ &\quad + \gamma \sum_a \pi(a \mid s) \sum_{s'} \mathbb{P}(s' \mid a, s) \mathbb{E}_{\pi}[G_{t+1} \mid S_{t+1} = s', S_t = s] \end{aligned}$$

Using the Markovian property,  $\mathbb{E}_{\pi}[G_{t+1} \mid S_{t+1}, S_t] = \mathbb{E}_{\pi}[G_{t+1} \mid S_{t+1}]$  so we get :

$$\begin{aligned} v_{\pi}(s) &= \sum_a \pi(a \mid s) \sum_{s'} \mathbb{P}(s' \mid a, s) [R(s') + \gamma \mathbb{E}_{\pi}[G_{t+1} \mid S_{t+1} = s']] \\ &= \sum_a \pi(a \mid s) \sum_{s'} \mathbb{P}(s' \mid a, s) [R(s') + \gamma v_{\pi}(s')] \end{aligned} \tag{1}$$

And the value of taking action  $a$  while being in state  $s$  under a policy  $\pi$  following roughly the same method:

$$\begin{aligned} q_{\pi}(s, a) &= \mathbb{E}[G_t \mid S_t = s, A_t = a] \\ &= \mathbb{E}\left[\sum_{k=0}^{\infty} \gamma^k r_{t+k+1} \mid S_t = s, A_t = a\right] \\ &= \sum_{s'} \mathbb{P}(s' \mid a, s) [R(s') + \gamma v_{\pi}(s')] \end{aligned} \tag{2}$$

We can see from (1) and (2) that :

$$v_{\pi}(s) = \sum_a \pi(a \mid s) q_{\pi}(s, a) \tag{3}$$

These equations are called the Bellman equations and are used to find the value functions using dynamic programming.

### 3 Optimal policies and Optimal value function

For finite MDPs, the value function can define a partial order in the space of policies :

$$\pi \leq \pi' \Leftrightarrow v_{\pi}(s) \leq v_{\pi'}(s) \quad \forall s \in \mathcal{S}$$

An optimal policy is a policy which is greater or equal than any other policy. This is what we are interested to find.

We can notice there is no policy strictly better than every deterministic policy (Puterman, 1994) so there is always a deterministic optimal policy since there is only a finite number of deterministic policies.

We may have multiple optimal policies but they all have the same value functions otherwise they would not be optimal policies with respect to the partial order define earlier. We denote these functions  $q_*$  and  $v_*$ .

**Bellman optimality equations** The optimal policy  $\pi^*$  has optimal value functions :  $v_*$  and  $q_*$ , which satisfy the relations below :

$$\begin{aligned} v_*(s) &= \max_a q_*(s, a) \\ &= \max_a \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma v_*(s')] \end{aligned} \quad (4)$$

$$\begin{aligned} q_*(s, a) &= \mathbb{E} [R_{t+1} + \gamma v_*(S_{t+1}) | S_t = s, A_t = a] \\ &= \mathbb{E} \left[ R_{t+1} + \gamma \max_{a'} q_*(S_{t+1}, a') | S_t = s, A_t = a \right] \\ &= \sum_{s'} \mathbb{P}(s' | s, a) [R(s') + \gamma \max_{a'} q_*(s', a')] \end{aligned} \quad (5)$$

These are called the *Bellman optimality equations*. What (4) tells intuitively is that the value of a state under  $\pi^*$  must equal the expected return for the best action we can take from that state.

For finite MDPs these equations have a unique solution. We can note that if we know  $v_*$  or  $q_*$  a greedy approach to define a policy (best in the short term) becomes a long-term optimal solution : indeed defining a policy being greedy in function of  $v_*$  implies that you go to the best state possible, the one with the biggest expected reward.

## 4 Solving MDPs with dynamic programming

In general we don't have all the information we need to compute the exact value of  $v_*$  or even if we have them, we don't have the computational power needed. We often use approximation of value-function instead.

From now on we assume our MDPs are finite, even if it is possible to extend everything to infinite MDPs if we are careful enough to avoid the problematic ones. (Sutton & Barto, 1998)

### 4.1 Policy iteration

This method uses two processes : the first one is policy evaluation : we compute the value function of a policy for all the states  $s \in \mathcal{S}$ ; then we use policy improvement to get a better policy by acting greedy.

**Policy evaluation** We begin by setting arbitrary  $v(s) \forall s \in \mathcal{S}$ . Then we update using one of the following update rules :

- $v_{k+1}(s) = \sum_{a \in A} \pi(a | s) \sum_{s'} \mathbb{P}(s' | a, s) (R(s') + \gamma v_k(s'))$  this is called "iterative policy evaluation".
- we can use the same update rule as before, but use new information as soon as it is available : this kind of upgrade algorithm are called in places.

From this we derive the algorithm 1.

**Policy improvement** Then we try to find a better policy : we try to determine whether we should change  $\pi(s)$  to  $a \neq \pi(s)$ . In order to do so, we try to first select action  $a$  while being in state  $s$  and then following the policy. If the expected reward we get by doing this choice is better than the one we get by simply following our policy, we should improve.

Mathematically speaking we will compare the value of taking action  $a$  while being in the state  $s$  :  $q_\pi(s, a)$  to the value of  $s$  :  $v_\pi(s)$ . Then we would greedily improve our policy this way.

The greedy update rule we use to improve our policy is the idea behind algorithm 2 :

$$\pi'(s) = \arg \max_{a \in A} q_\pi(s, a)$$

**Algorithm 1:** Iterative policy evaluation (in place)

---

**Input** : policy to evaluate  $\pi$   
**Output**:  $V \approx v_\pi$

```

1 Initialize  $V = 0$ 
2 while  $\Delta \geq \epsilon$  do
3    $\Delta = 0$ 
4   for  $s \in \mathcal{S}$  do
5      $v = V(s)$ 
6      $V(s) = \sum_a \pi(a | s) \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V(s')]$ 
7      $\Delta = \max(\Delta, |v - V(s)|)$ 
8   end
9 end
10 return  $V \approx v_\pi$ 

```

---

**Algorithm 2:** Policy improvement

---

**Input** : policy to improve  $\pi$   
**Output**:  $\pi'$  s.t :  $\pi' \geq \pi$

```

1 for  $s \in \mathcal{S}$  do
2    $\pi'(s) = \operatorname{argmax}_{a \in A} q_\pi(s, a)$ 
3 end
4 return  $\pi'$ 

```

---

**Policy Iteration** By combining the two processes described before, we can derive an algorithm to sweep through all our states and upgrade our policy until the changes between each sweep is too small : it is controlled by a parameter  $\epsilon$  and a parameter  $\gamma$  (which we talked about previously). This is the algorithm 3 which can be represented graphically by figure (2)

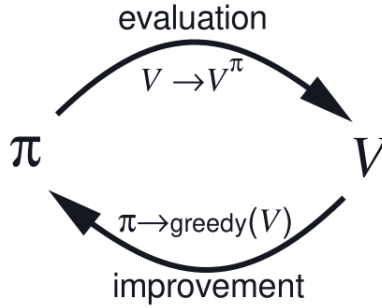

Figure 2: Graphical representation of the interactions between policy improvement and policy evaluation (from (Sutton & Barto, 1998))

Algorithm 3 terminates since there is only a finite number of deterministic policies. The reason why the algorithm 3 works is called the *policy improvement theorem*:

**Theorem 1.** Let  $\pi$  and  $\pi'$  be any pair of policies such that  $\forall s \in \mathcal{S}$  :

$$q_\pi(s, \pi(s)) \geq v_{\pi'}(s) \quad (6)$$

then :

$$\pi \geq \pi' \quad (7)$$

Moreover if there is a strict inequality in all the states in 6 then there must be at least a strict inequality for one state in 7

*Proof.* The idea of the proof is to expand the  $q_\pi$  side until we get  $v_{\pi'}(s)$  using Equation 2 in page 3. Indeed we have :

$$\begin{aligned}
v_\pi(s) &\leq q_\pi(s, \pi'(s)) \\
&= \mathbb{E}[r_{t+1} + \gamma v_\pi(S_{t+1}) \mid S_t = s, A_t = \pi'(a)] \\
&= \mathbb{E}_{\pi'}[r_{t+1} + \gamma v_\pi(S_{t+1}) \mid S_t = s] \\
&\leq \mathbb{E}_{\pi'}[r_{t+1} + \gamma q_\pi(S_{t+1}, \pi'(S_{t+1})) \mid S_t = s] \\
&= \mathbb{E}_{\pi'}[r_{t+1} + \gamma \mathbb{E}_{\pi'}[r_{t+2} + \gamma v_\pi(S_{t+2}) \mid S_{t+1} = s] \mid S_t = s] \\
&= \mathbb{E}_{\pi'}[r_{t+1} + \gamma r_{t+2} + \gamma^2 v_\pi(S_{t+2}) \mid S_t = s] \\
&\leq \dots \\
&= v_{\pi'}(s)
\end{aligned} \tag{8}$$

□

---

**Algorithm 3:** Policy Iteration

---

**Input** : arbitrary policy, stopping criterion  $\epsilon$   
**Output**: estimation of the optimal policy and of its value function

```

1 Policy evaluation :
2 while  $\Delta \geq \epsilon$  do
3    $\Delta = 0$ 
4   for  $s \in \mathcal{S}$  do
5      $v = V(s)$ 
6      $V(s) = \sum_a \pi(a \mid s) \sum_{s'} \mathbb{P}(s' \mid a, s) [R(s') + \gamma V(s')]$ 
7      $\Delta = \max(\Delta, |v - V(s)|)$ 
8   end
9 end
10 Policy improvement :
11 policy-stable = true
12 for  $s \in \mathcal{S}$  do
13   old-action =  $\pi(s)$ 
14    $\pi(s) = \operatorname{argmax}_{a \in A} q_\pi(s, a)$ 
15   if old-action  $\neq \pi(s)$  then
16     policy-stable = false
17   end
18 end
19 if policy-stable then
20   return  $V \approx v^*$  and  $\pi \approx \pi^*$ 
21 else
22   Go to Policy evaluation
23 end

```

---

## 4.2 Other types of DP method

**Value Iteration** Value iteration is another way of approximating an optimal policy : it combines in each of its sweep improvement and evaluation in algorithm 4.

**Algorithm 4:** Value iteration

---

**Input** : policy  
**Output**: estimate of optimal policy

```

1 Initialize V arbitrarily while  $\Delta \geq \epsilon$  do
2    $v = V(s)$ 
3    $V(s) = \max_a \sum_{s'} \mathbb{P}(s' | s, a) [R(s') + \gamma v_k(s')]$ 
4    $\Delta = \max(\Delta, |v - V(s)|)$ 
5 end
6 return  $\pi \approx \pi^* \text{ s.t. } \pi(s) = \operatorname{argmax}_a \sum_{s'} \mathbb{P}(s' | s, a) [R(s') + \gamma v_k(s')]$ 

```

---

Algorithm 4 finishes if the number of states is finite :

*Proof.* We define the Bellman operator :  $\mathcal{T} : \mathbb{R}^{|S|} \mapsto \mathbb{R}^{|S|}$  in the following way :

$$(\mathcal{T}V)(s) = \max_{a \in \mathcal{A}} \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V(s')]$$

In particular this operator is a contraction in the infinity norm, and hence our convergence is equivalent to the well known fixed point problem. Indeed if we consider the inequality :

$$| \max_z f(z) - \max_z h(z) | \leq \max_z | f(z) - h(z) | \quad (9)$$

Then having this inequality:

$$\begin{aligned}
| \mathcal{T}V(s) - \mathcal{T}V'(s) | &\leq | \max_{a \in \mathcal{A}} \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V(s')] - \max_{a \in \mathcal{A}} \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V'(s')] | \\
&\stackrel{(9)}{\leq} \max_{a \in \mathcal{A}} | \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V(s')] - \sum_{s'} \mathbb{P}(s' | a, s) [R(s') + \gamma V'(s')] | \\
&\leq \max_a \gamma | \sum_{s'} \mathbb{P}(s' | a, s) [V(s') - V'(s')] | \\
&\leq \gamma \max_s | V(s) - V'(s) | \\
&\leq \gamma \| V - V' \|_\infty
\end{aligned}$$

Now using the property that a contraction has a unique fixed point and that all sequences  $V, \mathcal{T}V, \mathcal{T}^2V, \dots$  converges towards this fixed point we get the convergence.  $\square$

There exists some others dynamic programming algorithm to solve these problems :

- Asynchronous Dynamic programming : it does not sweep amongst all the states at each iteration. They are in place iterative DP algorithms.
- General Policy Iteration (GPI): they are mixing the two components of policy iteration (evaluation and improvement) a little bit more than the algorithm we already saw.

But the most important drawback to these methods is that they are model-based, meaning that we need to have a complete knowledge of the model to implement those.

## 5 model-free approaches and algorithms

# Implementation

We have to determine our states, and hence a way for the robot to find its relative distance to our traffic light.

## 6 States

### 6.1 Distance to the traffic light

### 6.2 Speed

## 7 Reward function
